

The strange energy spectrum of MPS ground states

with Max Silvester and Giuseppe Carleo

1. Introduction to DMRG
2. Extrapolation with truncation error and with the energy variance
3. Perfect Sampling; fat tails for the variance
4. The unusual energy spectrum
5. Improved extrapolations

Max Silvester

Intro to DMRG

Diagrams: matrix multiply $\sum_j A_{ij} B_{jk}$

External lines: usually physical states
 Internal: summed over

Periodic Matrix Product State

Hamiltonians: simple, usually local

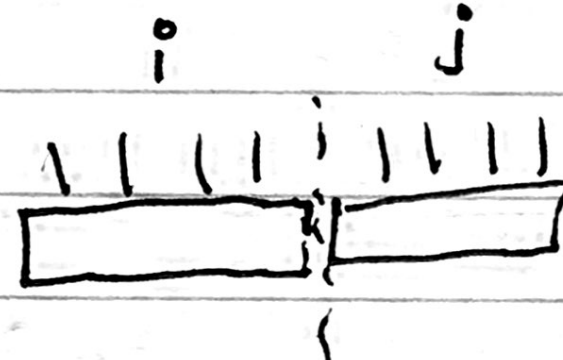

e.g. Heisenberg $H = \sum_{\langle ij \rangle} J \vec{S}_i \cdot \vec{S}_j$

The Hilbert space is always exponentially large, but physical sites live on a lattice in 1D, 2D, or 3D

Both are written as tensor networks
 Matrix Product State (MPS) or MP operator
 MPO

If we cut a wavefunction in two,
we can do an SVD

$$\psi_{ij} = U_i \lambda D_\lambda V_j^T$$
 Schmidt Decomposition

The key to tensor networks is that
the singular values are mostly near
zero

If we retain only
m values, the

~~exact~~ exact truncation error is $\sum_{\lambda=m+1}^{\infty} \lambda^2$

$= \epsilon_{\text{exact}}$. This is a measure of the
error in the wavefunction.

The von Neumann entanglement entropy is

$$S = - \sum_{\lambda} \lambda^2 \ln \lambda^2$$

For ground states, S is small —
the area of the cut 
(Area Law). For Area law states in 1D,

an MPS is ideal

N=8

Energy levels of $S=1/2$ Heisenberg chains

N=12

Bulk eigenstates are “super-entangled”

Von Neumann Entanglement entropy S for every eigenstate (system divided in center)

Entanglement entropy of the ground state of N-site Heisenberg chains

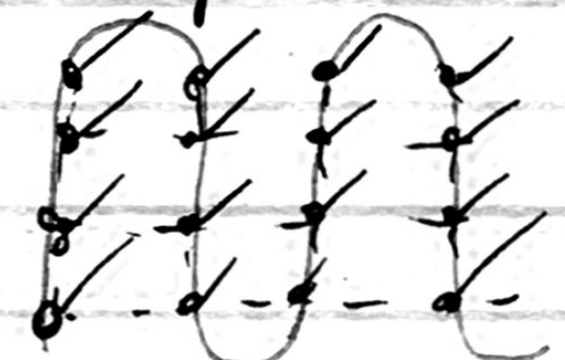

$S=1$: gapped, bigger d , edge spinons

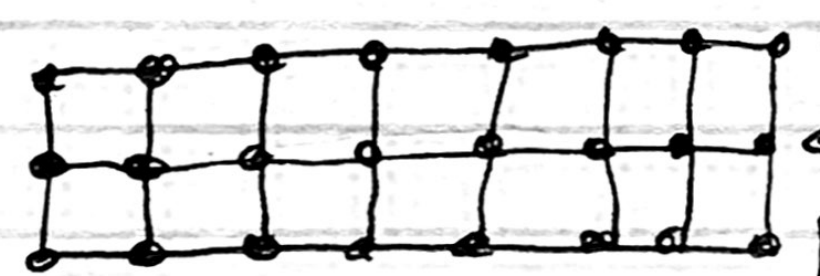

$S=1/2$: gapless, log correction, “RVB” oscillations

System are cut in two, symmetrically, with open boundaries

(Doing all these systems with DMRG took just a few minutes on my laptop)

For 2D problems, we can study a strip or cylinder with a snake path

 Computationally efficient ground state exponentially with the width.

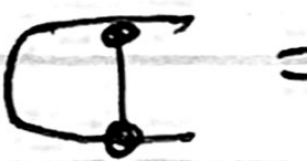

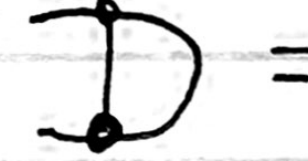

(For wide widths, should use a 2D TN with an MPS for ψ & MPO for H ,

$$E = \langle \psi | H | \psi \rangle = \langle \chi | H | \chi \rangle$$

H-MPO:  $w \sim 3-5$ simple 1D
 $\sim 20-40$ wide 2D
 $\sim 100-1000$ quantum chemistry

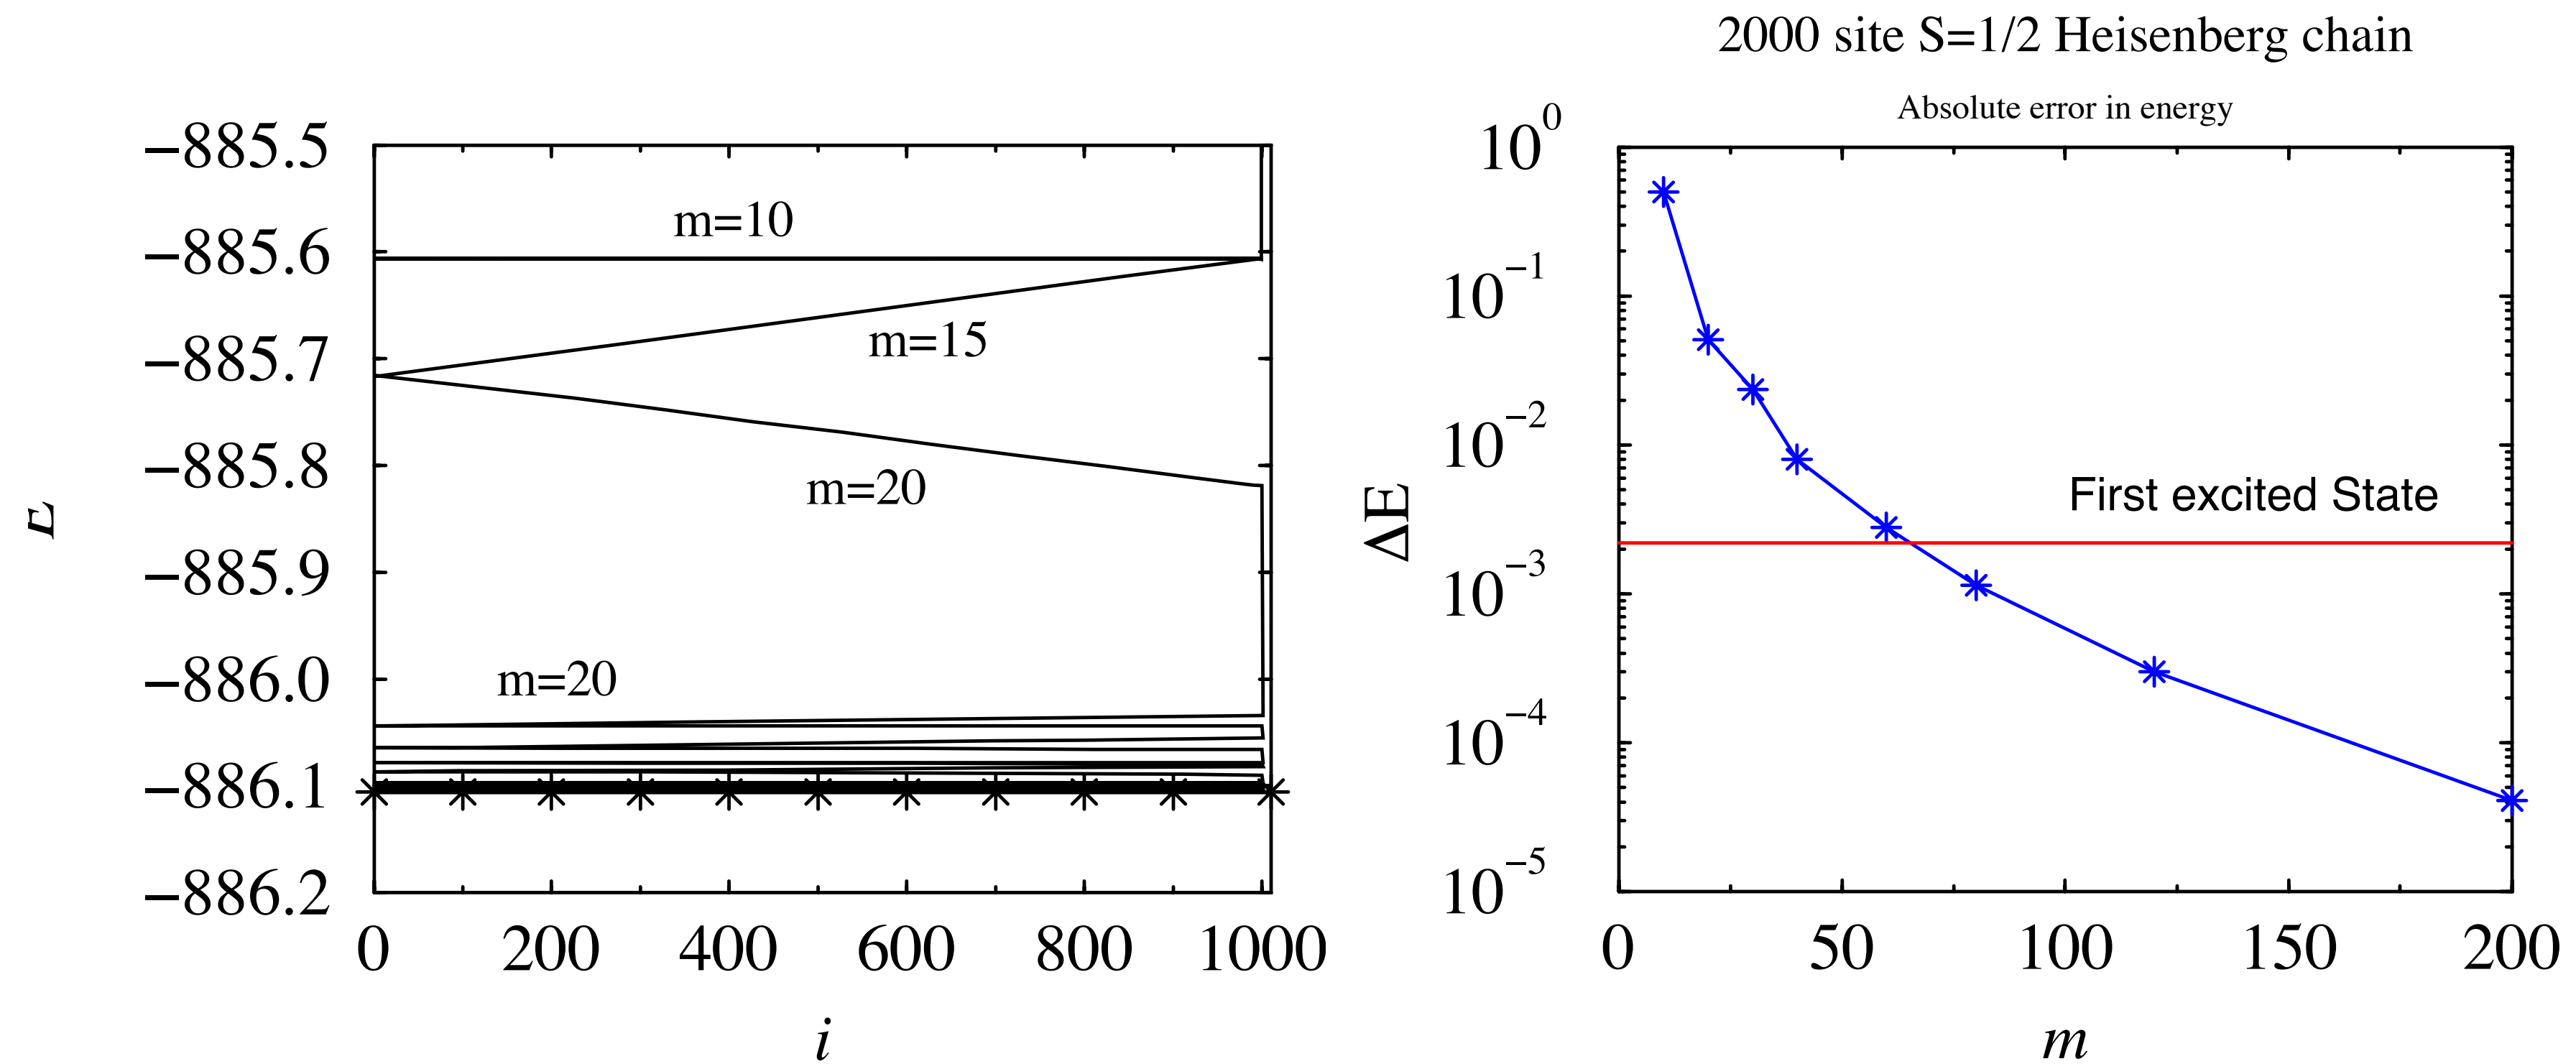

The density matrix renormalization group (DMRG) finds ψ & E with

- 1) Alternating least squares (sweeping)
- 2) Gauge choices / tensor orthogonality to create orthonormal subspaces

e.g.  = (or  =)

- 3) Efficient Lanczos or Davidson in the subspaces

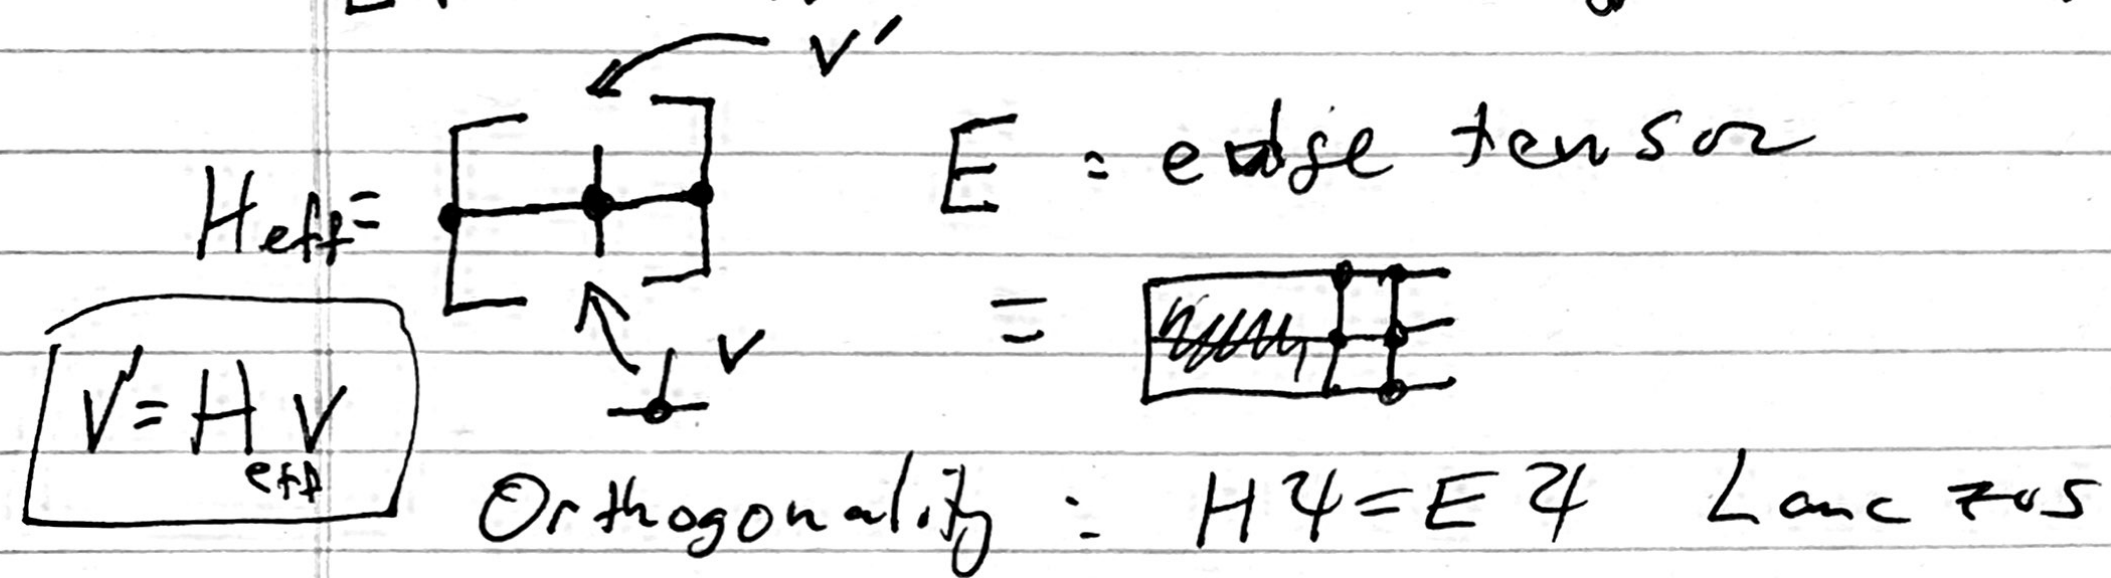

Convergence in ID

Comparison with Bethe Ansatz

Effective Hamiltonian during a sweep:

Two site algorithm:

(a) Find optimal two-site V

(b) SVD to factorize it $\left[\text{---} \bullet \text{---} \bullet \text{---} \right] = \left[\text{---} \bullet \text{---} \right] \left[\text{---} \bullet \text{---} \right]$
with truncation m

This:

(a) Speeds convergence significantly

(b) Allows m to increase efficiently

(c) Gives an estimate of the truncation

error $\epsilon = \sum_{m+1}^{\infty} D_{\lambda}^2$

which can be used to extrapolate E

very useful but
delicate

Energy extrapolation

Assign error bars to result:
if the fit is this good,
assign (extrapolation from
last point)/5

(no derivation, just
experience that this works
on lots of systems)

If the fit looks worse,
increase the error bar
(substantially) or don't use
that run/keep more states
or smaller size system.

Probability of states thrown away
= truncation error (function of m)

Weaknesses of truncated error extrapolation

1) Tied to 2-site algorithm and sweeping history (increase of m)

2) May fail for non-local Hams (quantum chemistry)

What about variance extrapolation?

$$\begin{aligned}\sigma^2 &= \langle \psi | (H - E)^2 | \psi \rangle = 0 \text{ for any eigenstate} \\ &= \langle \psi | H^2 | \psi \rangle - E^2 \quad E = \langle \psi | H | \psi \rangle\end{aligned}$$

Contraction time $\sim m^3 W^2 N$

VS $m^3 W N$ for DMRG \rightarrow extra factor of W

Can this be sped up with sampling?

Prob of a spin config: $P(s_1, s_2, \dots) = |\psi(s_1, s_2, \dots)|^2$

There are Markov chain methods to sample/sweeps, but we don't need them

— perfect sampling —

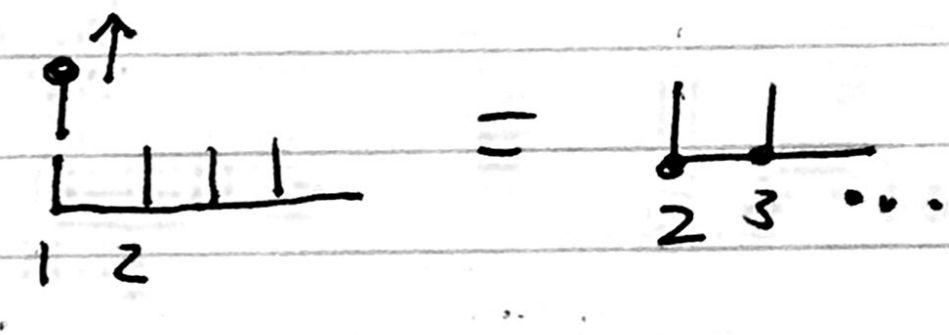

Perfect Sampling - Mimics Physical Measurement

Measuring bit by bit gives the same $P(s \dots)$ as all at once.

1. Adjust orthogonalities center to site 1
 $D = \uparrow$ on site $2 \dots N$

2. Single site density matrix $\rho = \rho$
 gives $P(\uparrow) + P(\downarrow)$ choose
 with random # gen.

3. Apply ~~project~~ state obtained to MPS site

Repeat for all sites

Perfect indep sampling from $P(s_1, s_2 \dots)$

Cost Nm^2 /sample

$$E = \langle \psi | H | \psi \rangle = \sum_s \langle \psi | s \rangle \langle s | H | \psi \rangle$$

$$= \sum_s P(s) \frac{\langle s | H | \psi \rangle}{\langle s | \psi \rangle}$$

$\langle s | H | \psi \rangle$ cost Nm^2
 but already have E

$$\sigma^2 = \sum_s \langle \psi | H - E | s \rangle \langle s | H - E | \psi \rangle$$

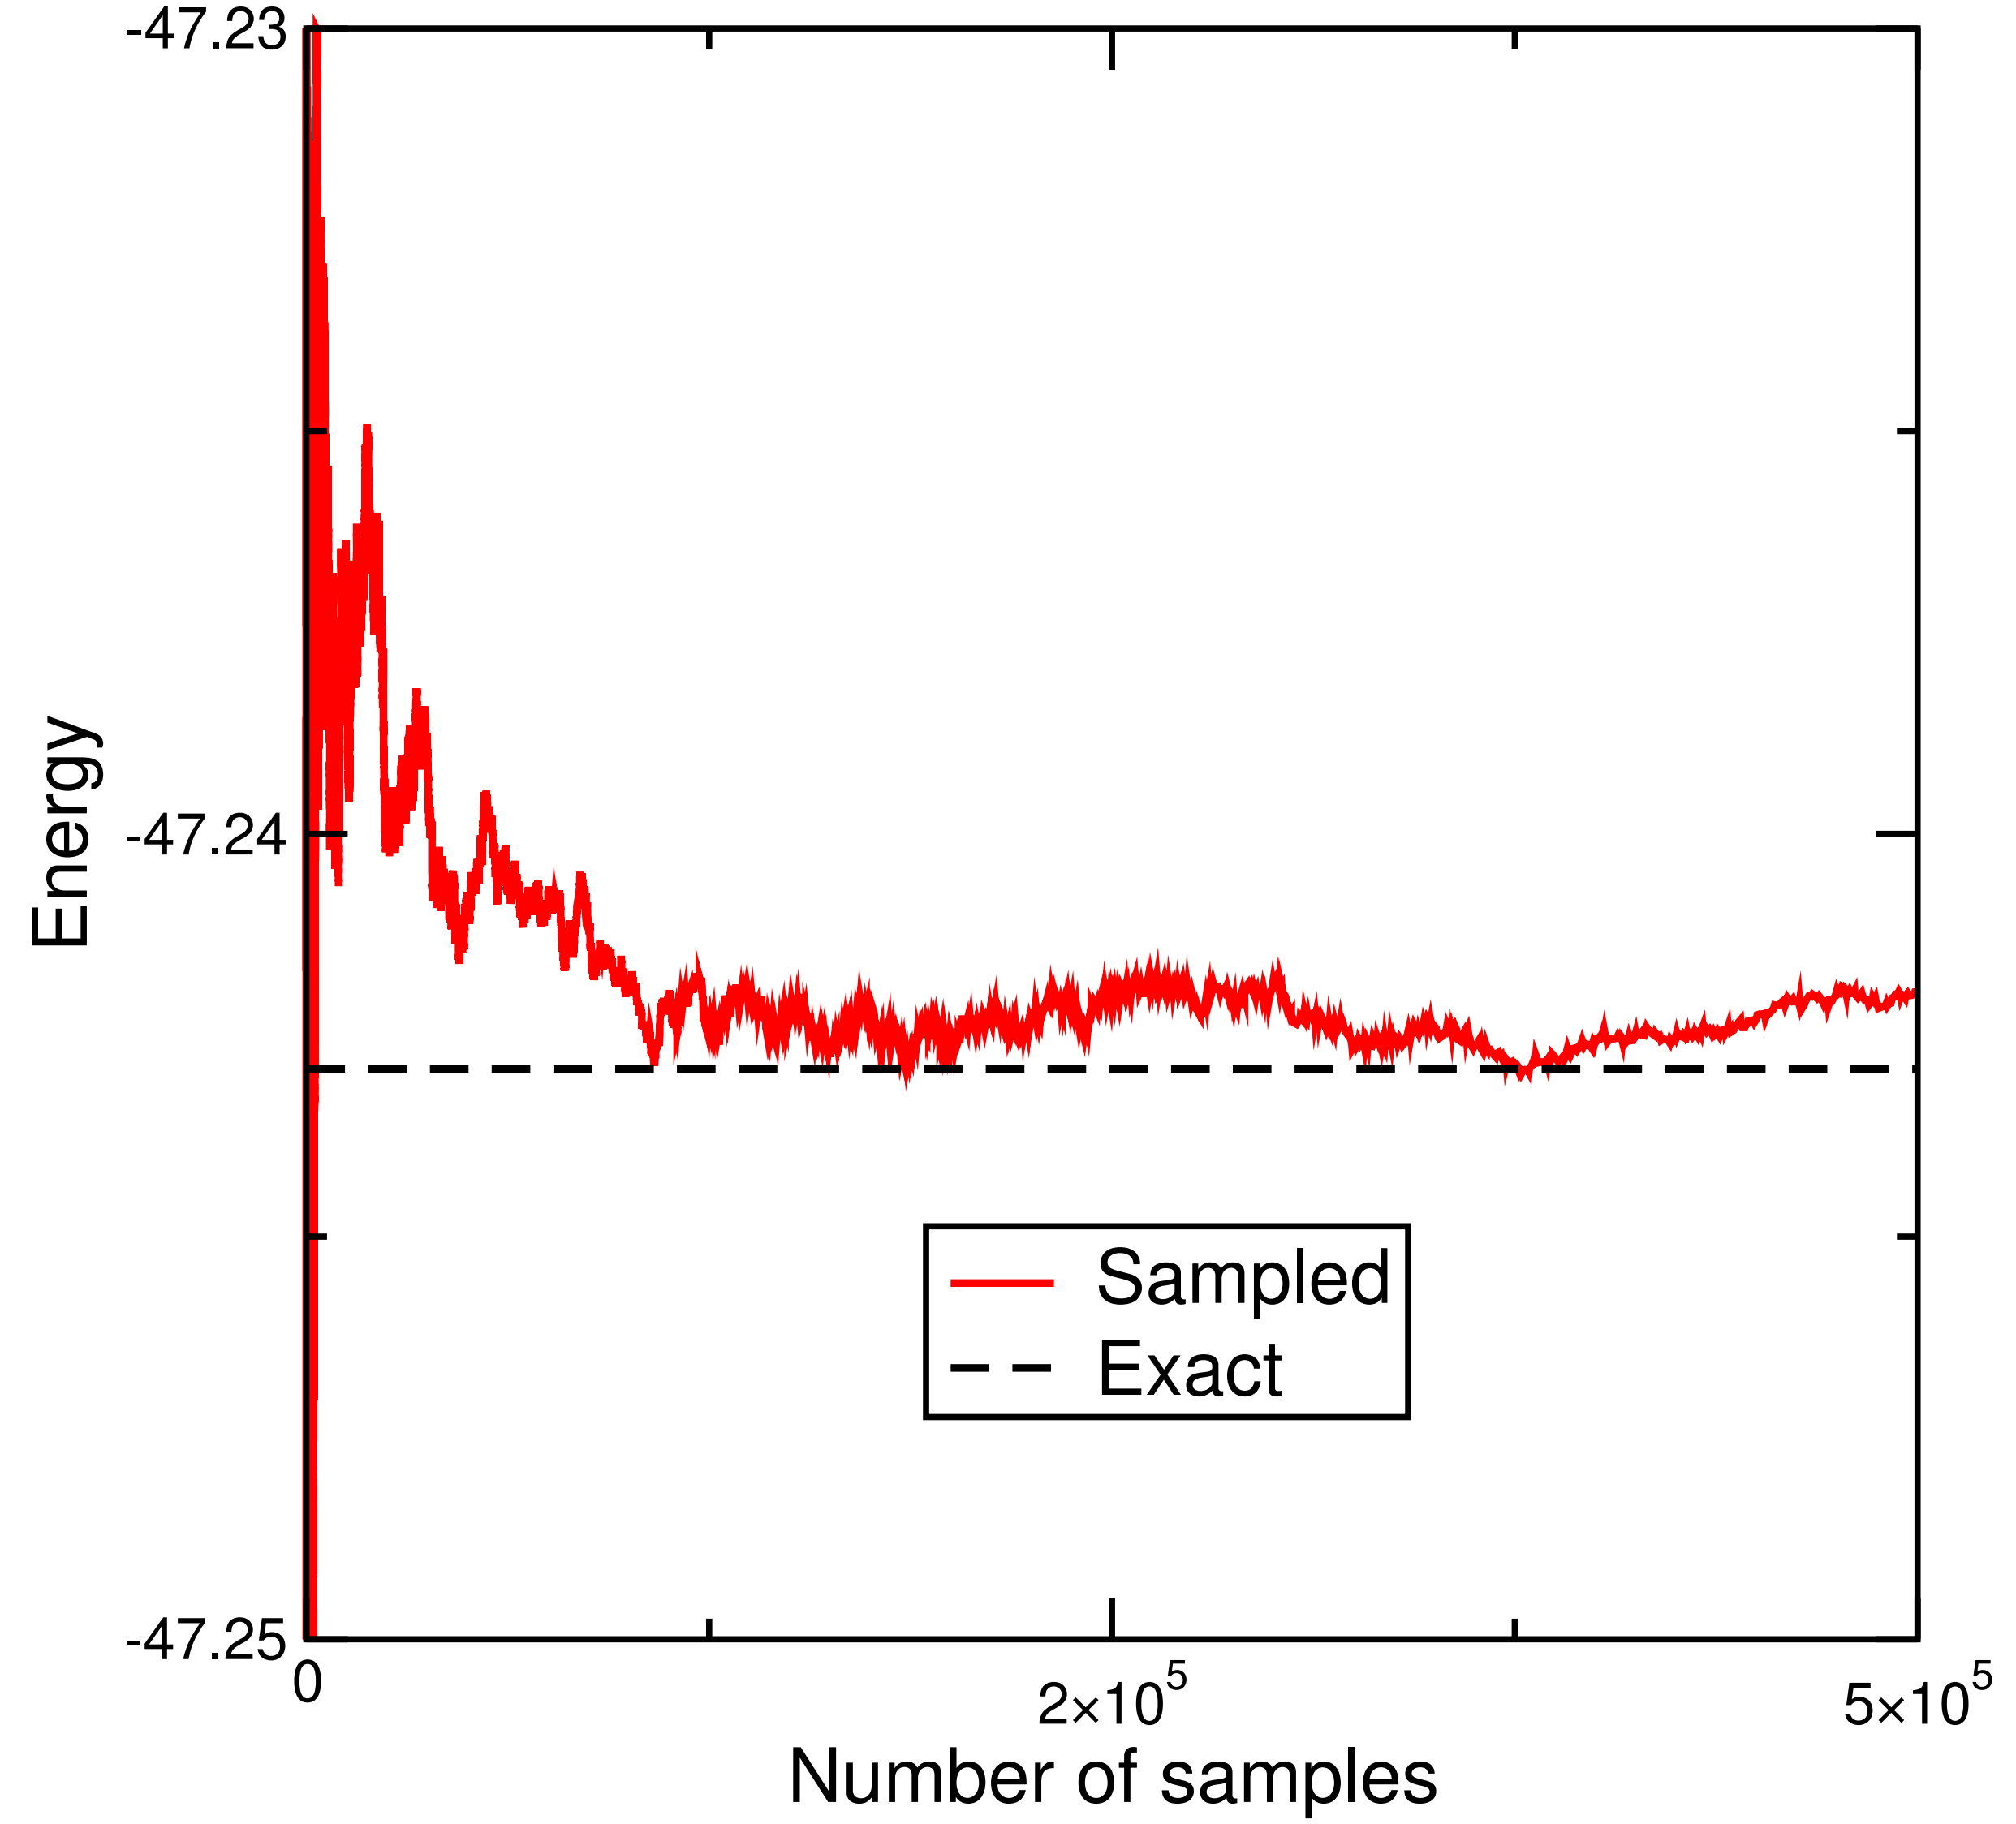

$$= \Delta_s + \sum_{s \text{ s.t. } P(s) \neq 0} P(s) (E_s^L - E)^2$$

$$E_s^L = \frac{\langle s | H | \psi \rangle}{\langle s | \psi \rangle}$$

Bias in sampling σ^2

Energy sampling

Running Average

12x6 Heisenberg
square lattice

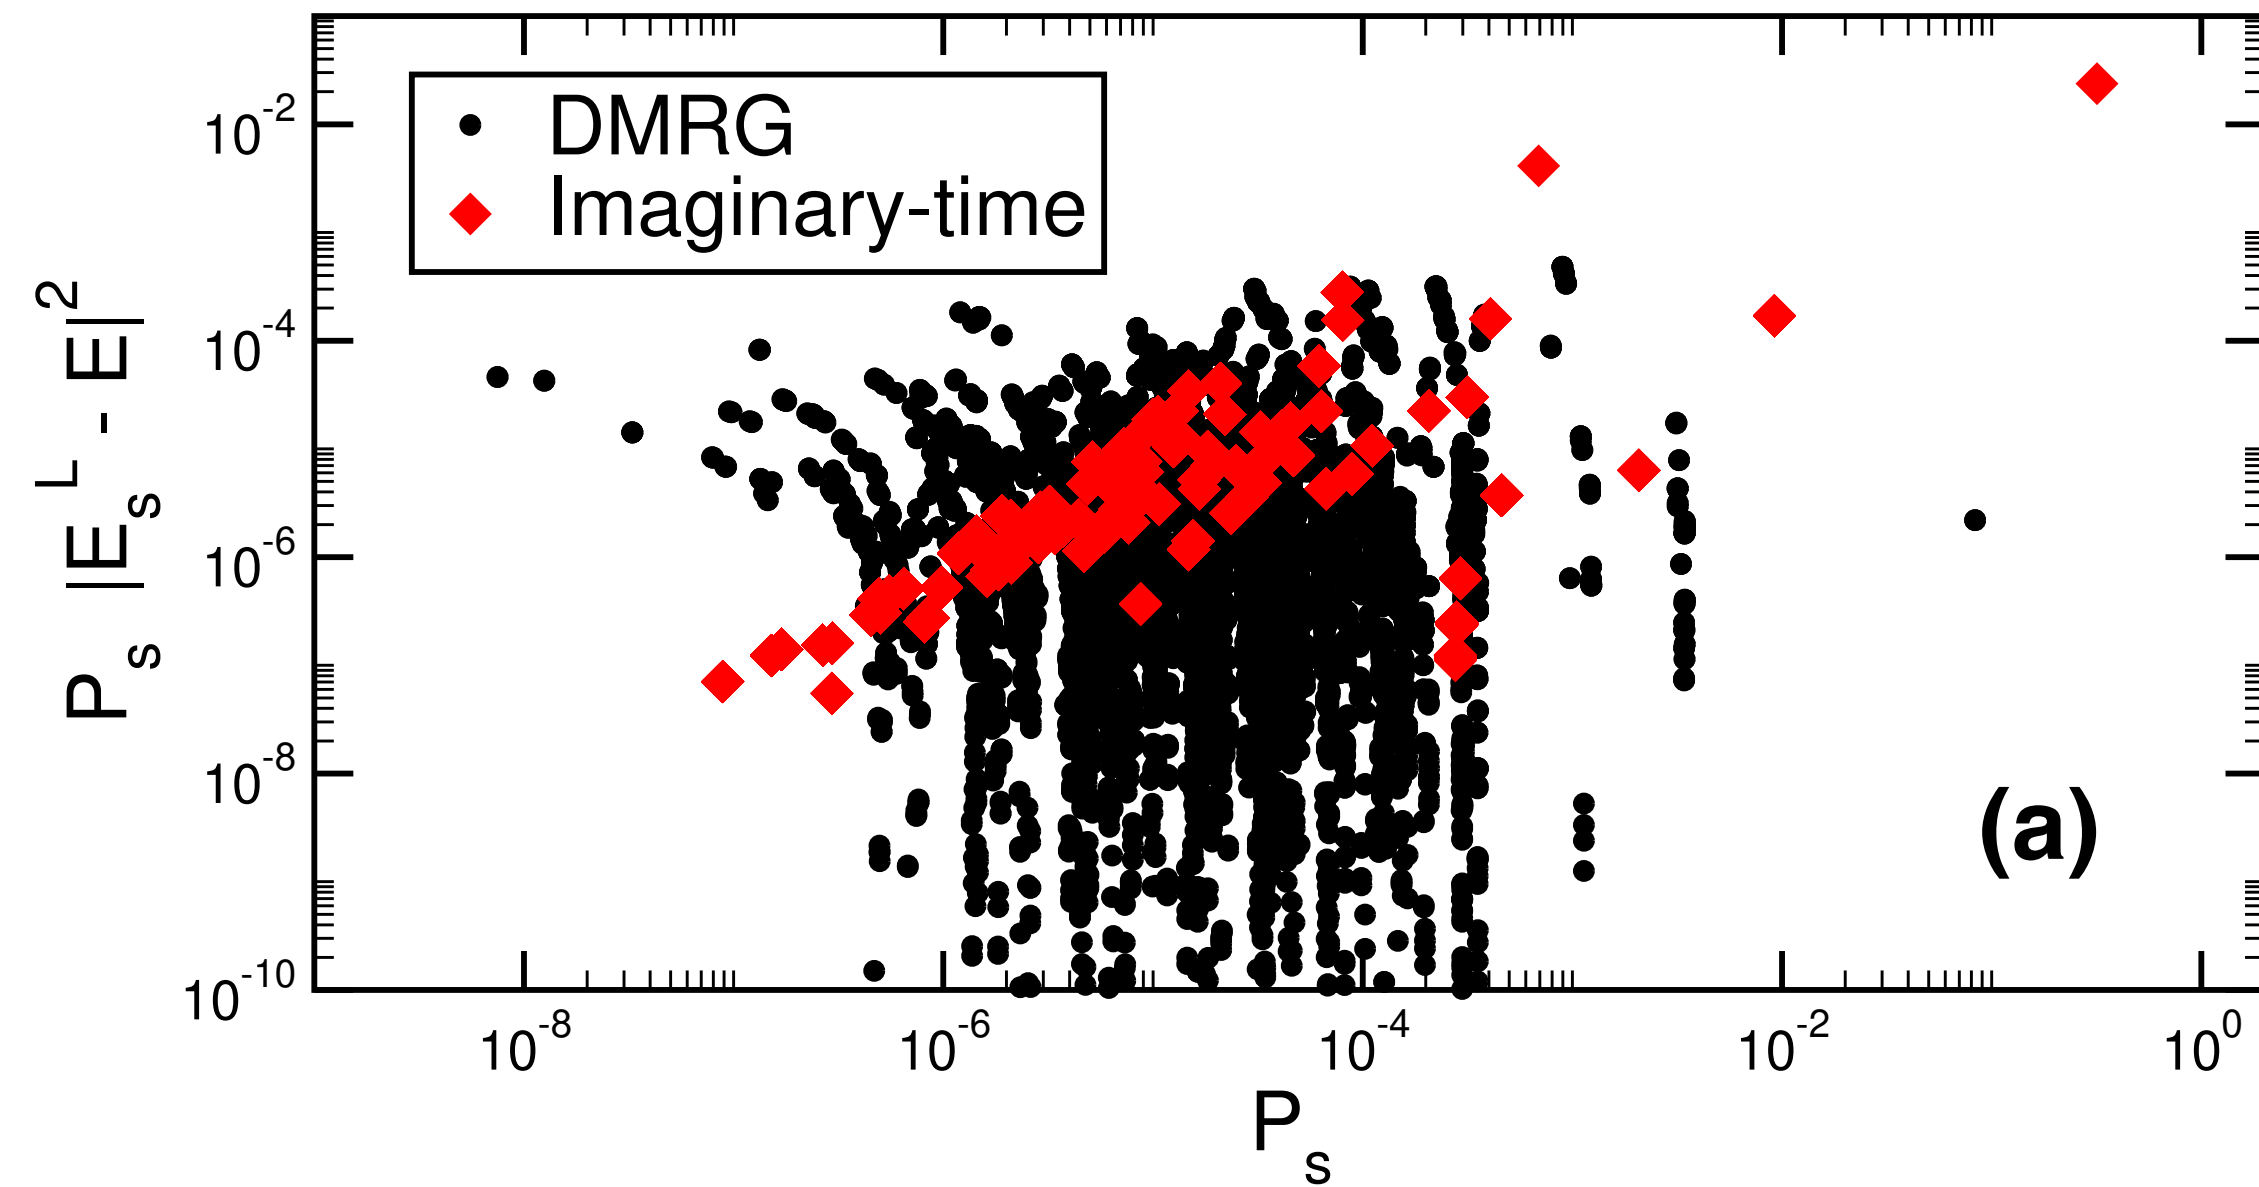

$m = 120$

Variance sampling

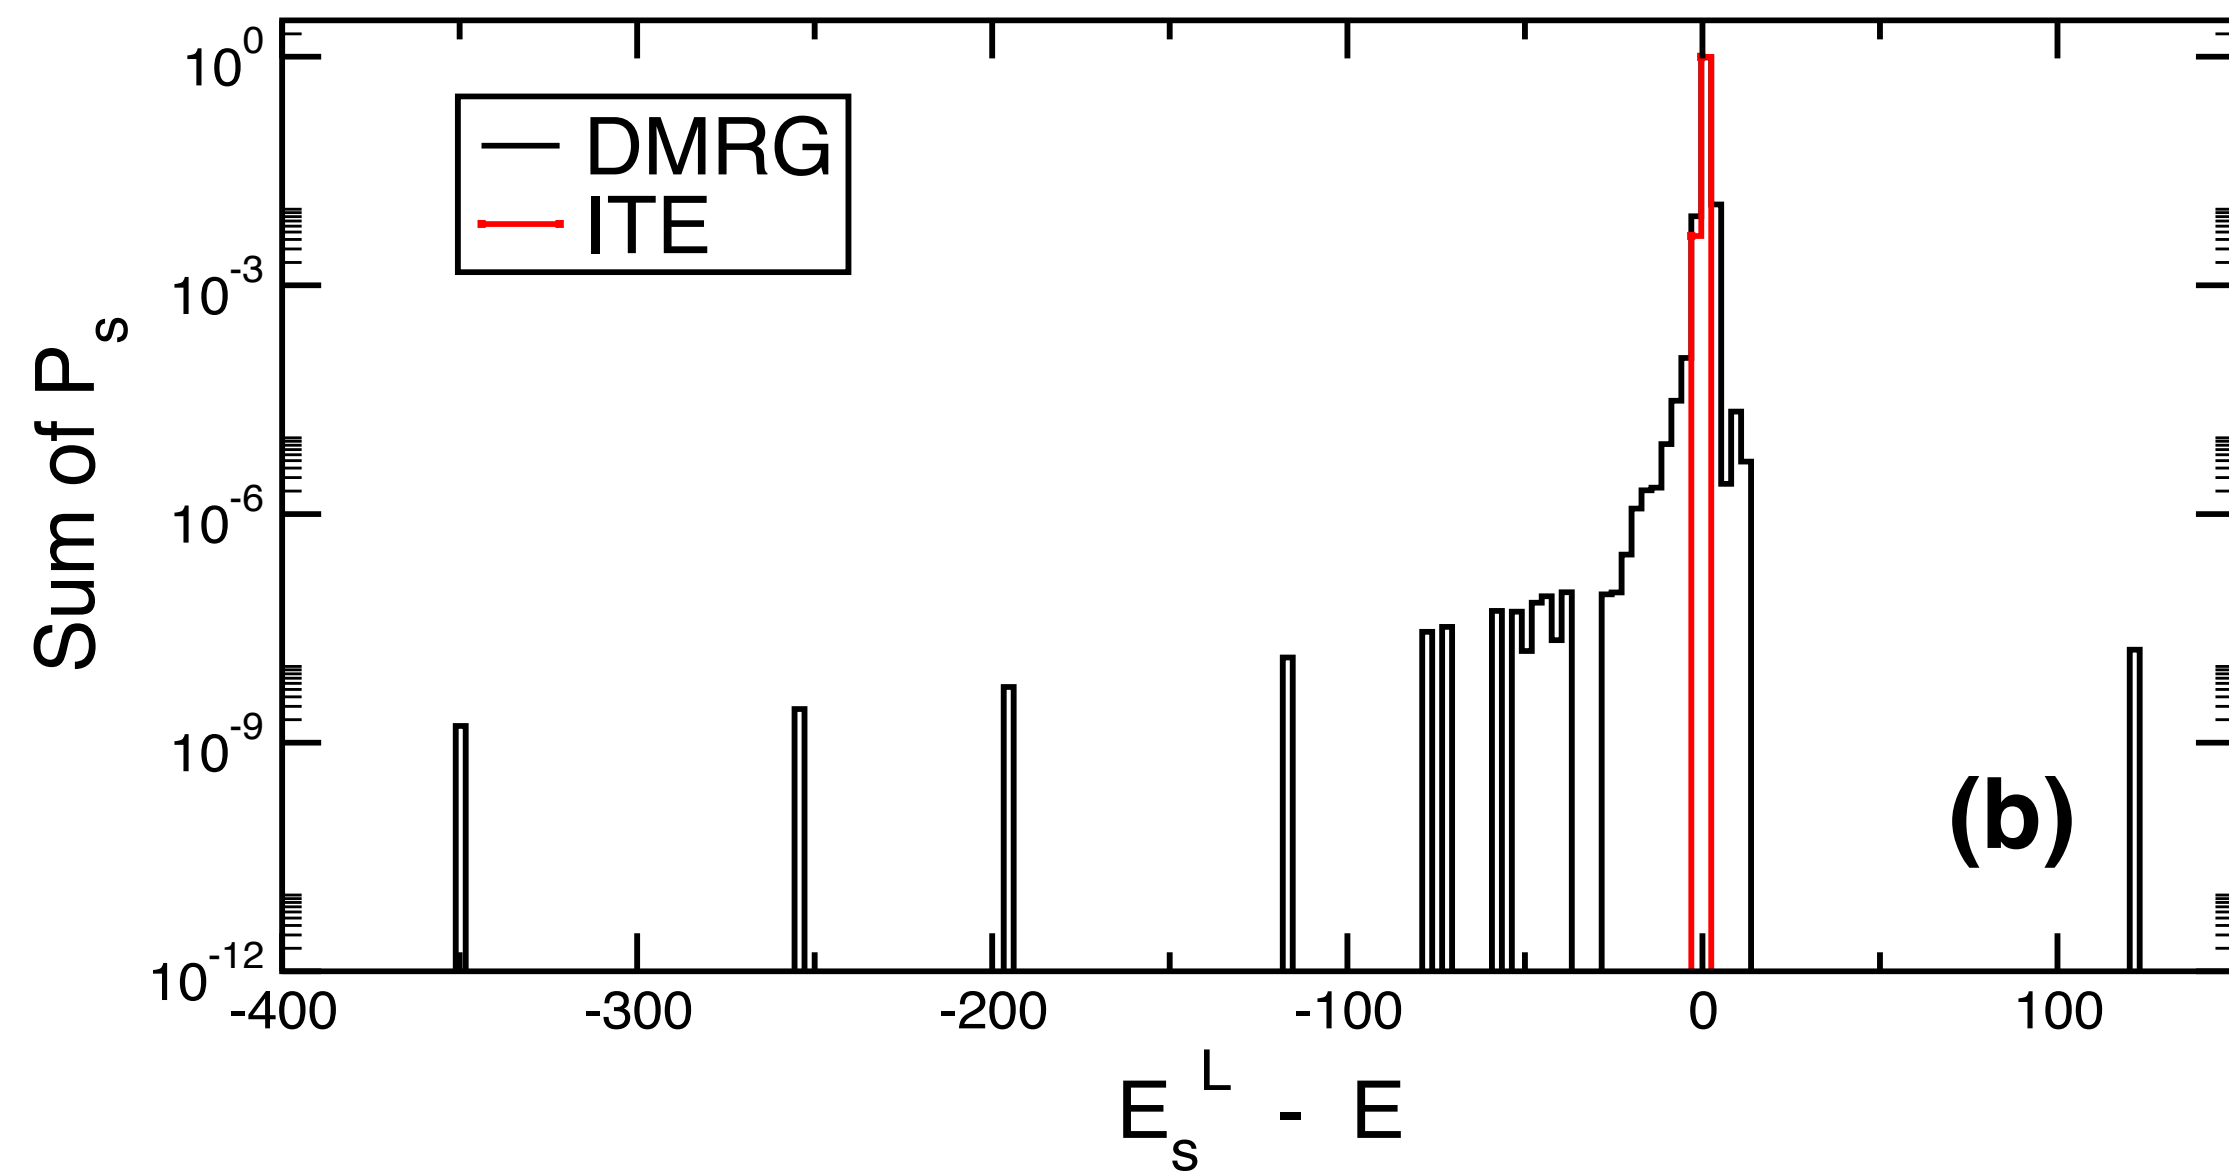

4x4 Heisenberg square lattice torus (pbc) $m = 80$

Small system exact calculation

Here we compare the sampling distribution for a DMRG wavefunction and a wavefunction obtained from imaginary time evolution. We plot the contribution to the variance of each sample. (4x4 torus)

Histogram of distribution of E-local, DMRG versus imaginary time evolution

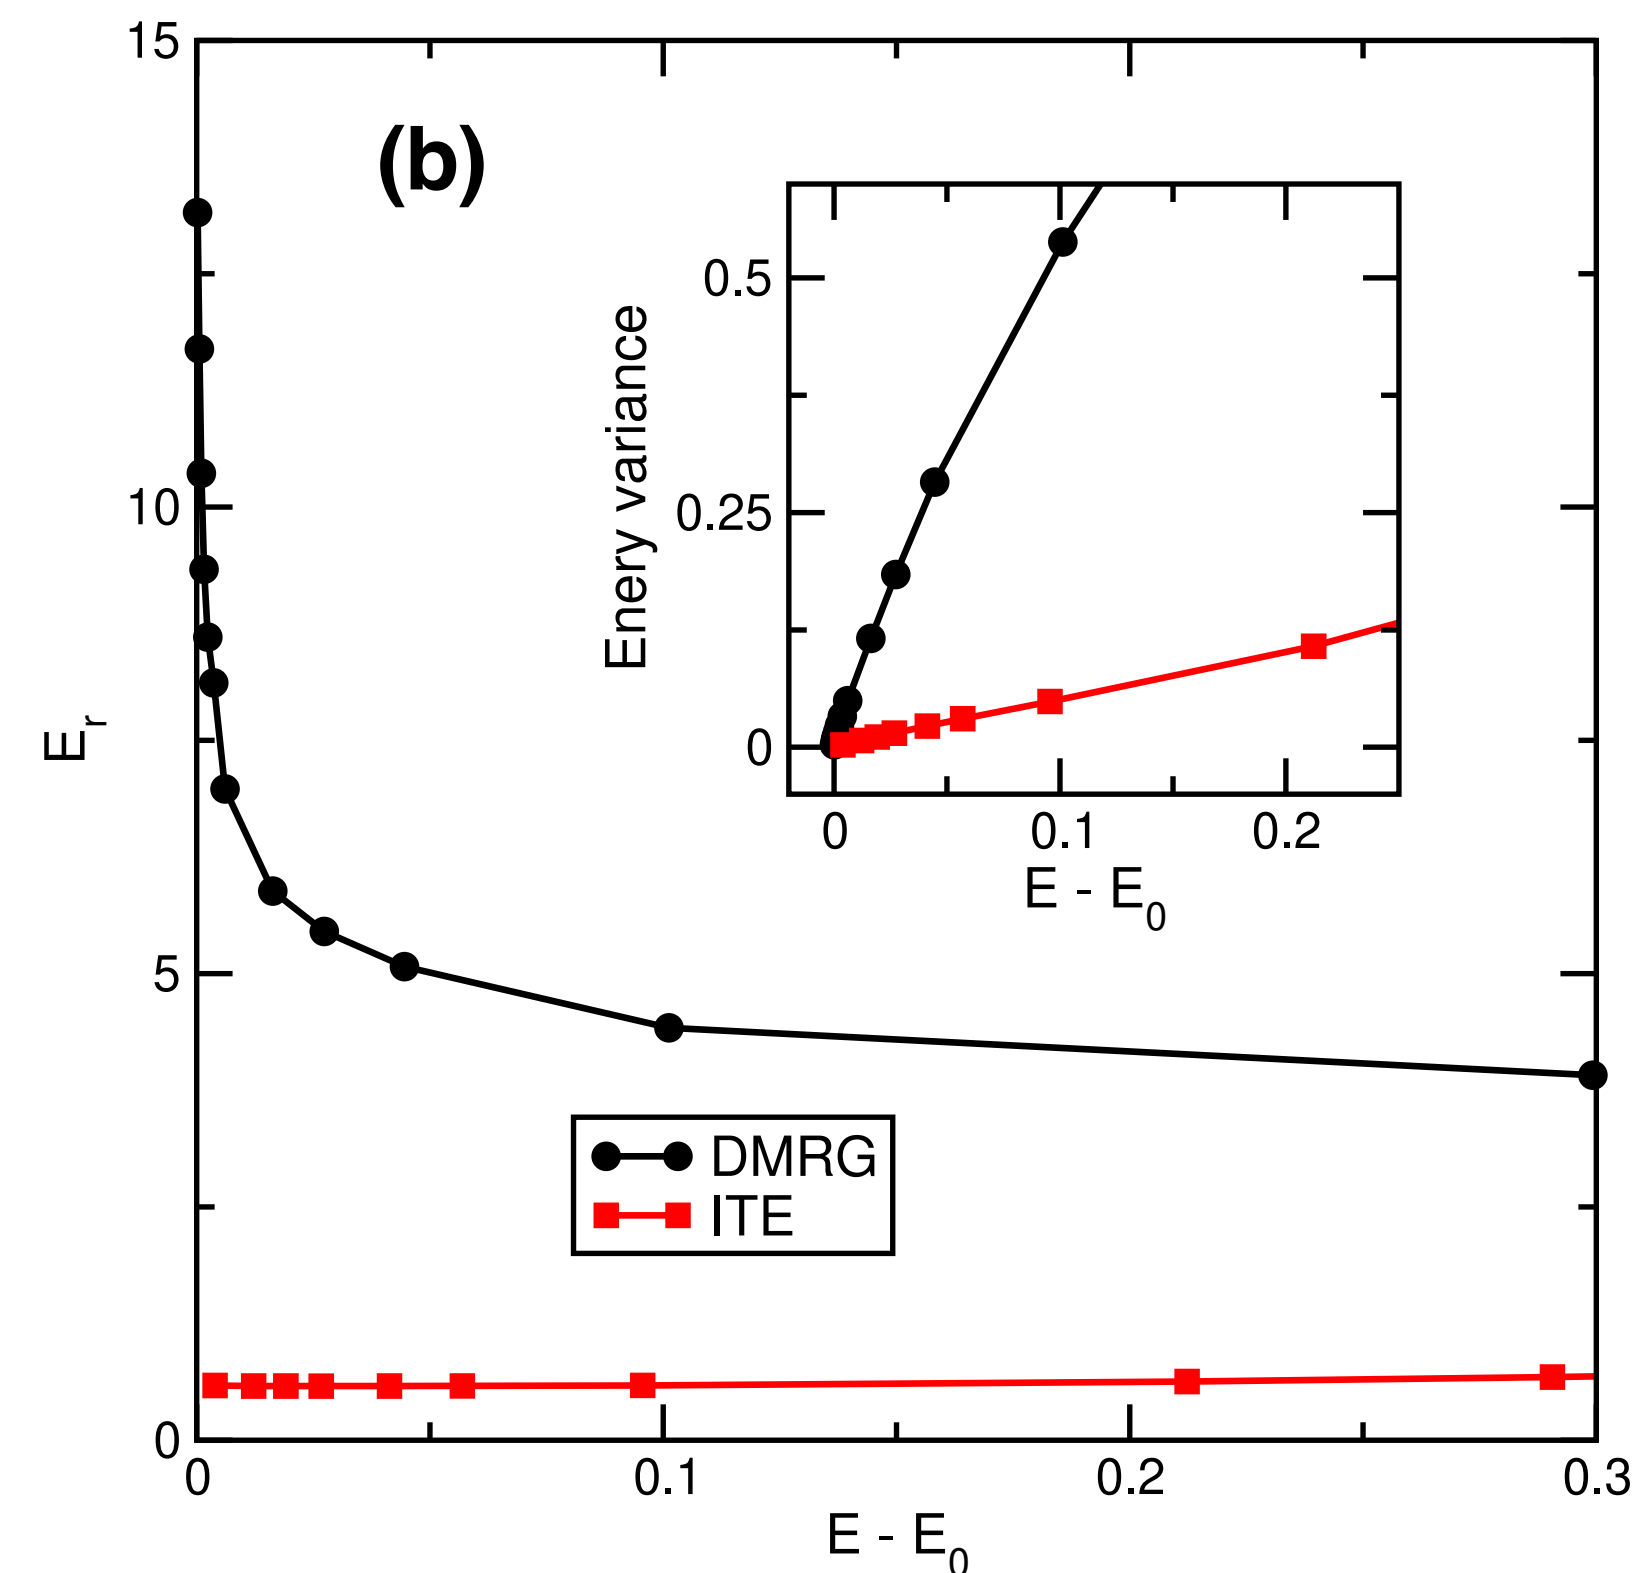

Energy Spectrum

To try to understand this, we decomposed the approximate ground states into superpositions of exact eigenstates

$$|\psi\rangle = \sum_n c_n |n\rangle \quad n \text{ an eigenstate}$$

We can look at the average energy of the excited state part of the wavefunction E_r as we increase the bond dimension (move to left)

Why do DMRG states have this strange Energy Spectrum?

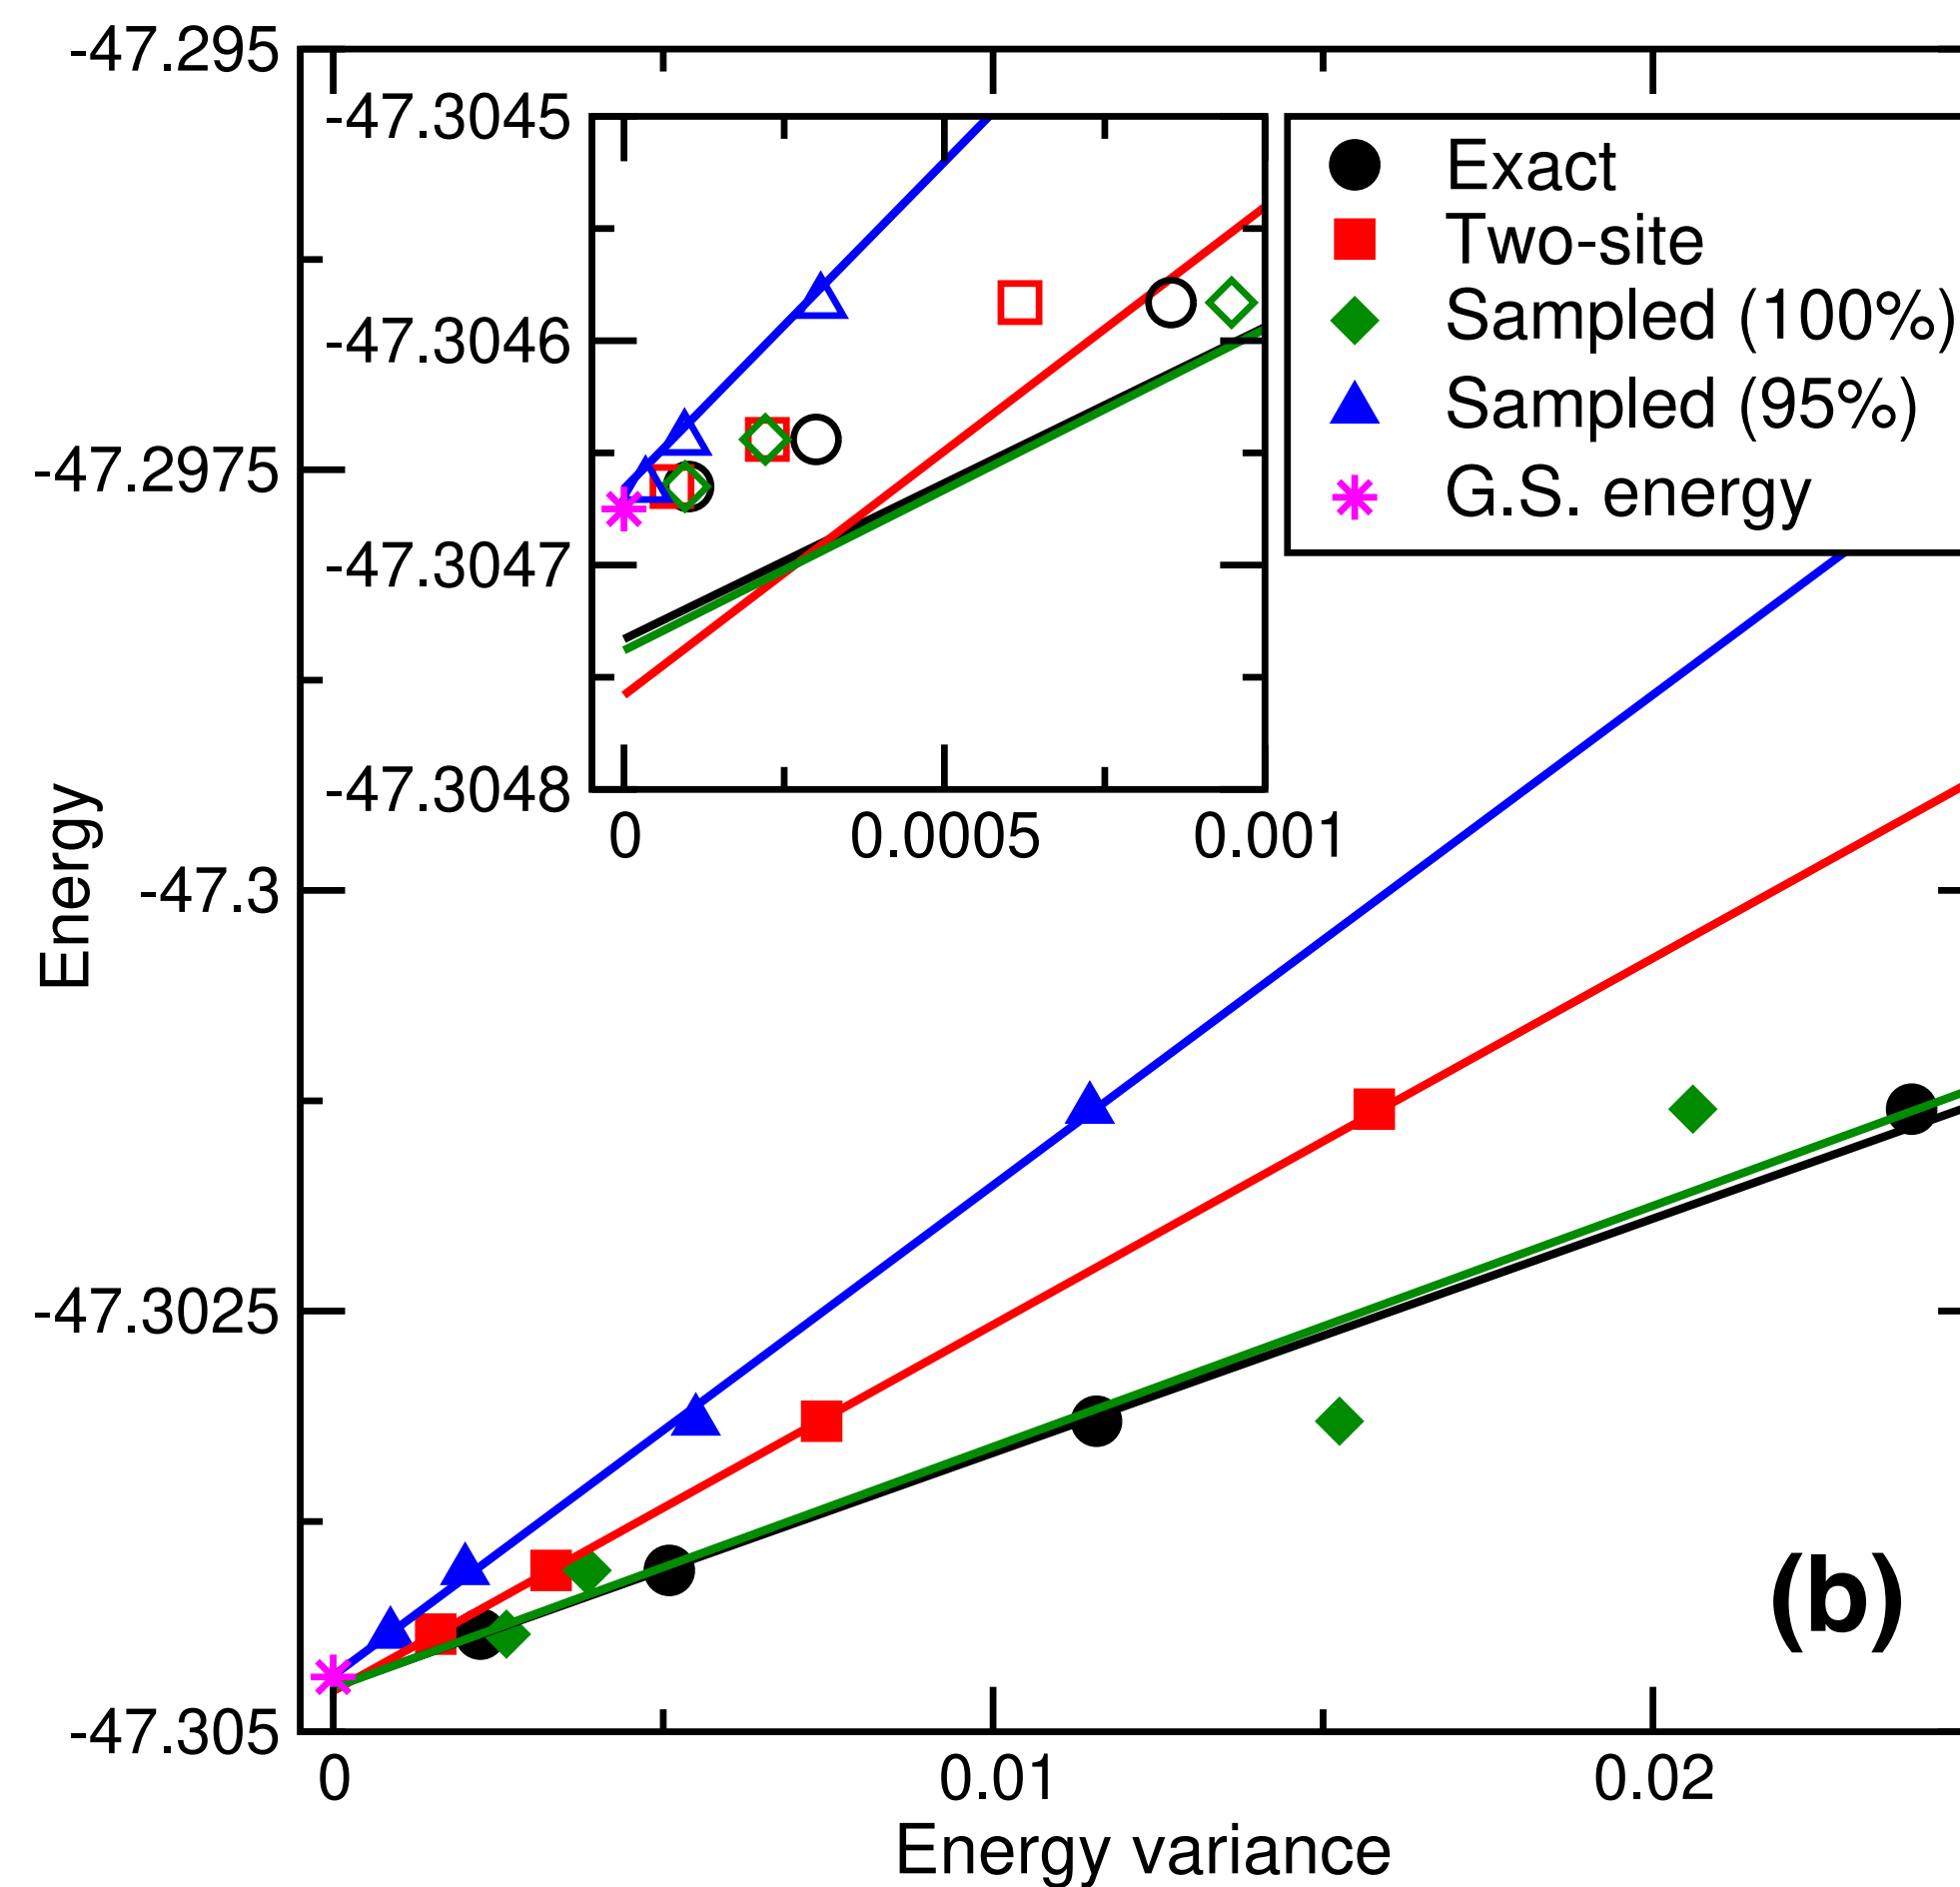

Optimized MPS ground states satisfy two criteria: low energy, and small bond dimension. This is incompatible with being a superposition of a few low energy states.

Suppose, for high accuracy, we needed $m \sim 1000$ for the ground state. Low lying states are slightly more entangled, but say we still need $m \sim 1000$ for them. Say our approximate MPS has $m=100$. If it was a superposition of the excited states, it would say a few MPS with high bond dimension could combine and cancel out almost all the high bond dimension parts.

Apparently, the only way to get low bond dimension is a superposition of many states — which must have a broad spectrum.

Can we revive our extrapolation based on sampled variance?

Suppose we impose a window on our sampled E-local, throwing away extreme samples. This is highly biased, but the bias goes away as the bond dimension increases. If the bias decreases smoothly, the extrapolation can deal with it.

We actually find better extrapolations with the truncated sampled method (at 95%) than any of the alternatives — truncation error, exact variance, two site variance...

Conclusions

DMRG ground states inherently have a strange energy spectrum: lots of weight in the exact ground state, and very spread out tiny contributions going to very high energies! This is very different from imaginary time approximate wavefunctions.

Biased truncated energy extrapolations work quite well, providing an excellent alternative to truncation error extrapolations.

Extrapolation of the energy

Extrapolation improves the energy by a factor of 5-10 and provides an error estimate.
